HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

SUMMING A POLYNOMIAL FUNCTION OVER INTEGRAL POINTS OF A POLYGON. USER'S GUIDE.

VELLEDA BALDONI, NICOLE BERLINE, AND MICHÈLE VERGNE

ABSTRACT. This document is a companion for the Maple program **Summing a polynomial function over integral points of a polygon**. It contains two parts. First, we see what this programs does. In the second part, we briefly recall the mathematical background.

1. INTRODUCTION

The present article is a user's guide for the Maple program **Summing a polynomial function over integral points of a polygon**, available at <http://www.math.polytechnique.fr/~berline/maple.html>. The Maple program contains two types of computation. The first computation does just what the title says. The input consists of a finite set of rational points in \mathbb{Q}^2 , whose convex hull is a polygon \mathbf{p} , and a polynomial $h(x, y)$ with rational coefficients. The output is the sum

$$\sum_{(x,y) \in \mathbf{p} \cap \mathbb{Z}^2} h(x, y).$$

The second computation returns the function of $t \in \mathbb{N}$ which arises when the polytope \mathbf{p} is dilated by t .

$$E(t) := \sum_{(x,y) \in t\mathbf{p} \cap \mathbb{Z}^2} h(x, y).$$

This function is a *quasi-polynomial*, meaning that it has the form

$$E(t) = \sum_{i=0}^{\deg h + 2} E_i(t) t^i,$$

where the coefficients depend only on $t \bmod q$, where q is the smallest integer such that $q\mathbf{p}$ has integral vertices. The function $E(t)$ is called the *weighted Ehrhart quasi-polynomial* of \mathbf{p} with respect to the weight $h(x, y)$.

Date: May 2009.

We apply two methods, the first one for a fixed polygon, the second one for the computation of the weighted Ehrhart quasi-polynomial. The first method is based directly on Brion's formula (2), [3], while the second method is based on the local Euler-Maclaurin formula of [2]. Both methods use Barvinok's decomposition into unimodular cones [1]. Although they are very similar, the first method is faster when we deal with a fixed polygon, while the second is faster when we want the Ehrhart quasi-polynomial.

The software libraries *LattE* [4] (improved version in [5]) and *Barvinok* [6] include the computation of the number of points of a rational polytope in any dimension, together with many other applications. Moreover, the weighted Ehrhart polynomials in any dimension are computed in *Barvinok*. The present program, in dimension two, is based on the same principles: Brion's formula and Barvinok's decomposition of cones. We use however some new ideas on "renormalisation" of Laurent series from [2] to speed up the computation. In the future, we will generalize it to higher dimensions.

2. MAIN COMMANDS

2.1. Summing a polynomial function over the set of integral points of a polygon. Let $P \subset \mathbb{Q}^2$ be a finite set of points. Let $\mathbf{p} \subset \mathbb{R}^2$ be the polygon obtained as the convex hull of the set P . The program computes the sum

$$\sum_{(x,y) \in \mathbf{p} \cap \mathbb{Z}^2} h(x,y)$$

of the values of a polynomial $h(x,y)$ over the set of integral points contained in \mathbf{p} . In particular, when $h = 1$, it computes the number of integral points in \mathbf{p} .

For a single monomial $h(x,y) = x^{m_1}y^{m_2}$, the command is

```
>sum_monomial_polygon(P,m);
```

Here P is a set of pairs of rational numbers, and $m = [m_1, m_2]$ is a pair of non negative integers, the multidegree of the monomial $x^{m_1}y^{m_2}$.

If we want just the number of integral of integral points, we can use the command

```
>number_points_polygon(P);
```

This number can be also obtained by the command

```
>sum_monomial_polygon(polygon,[0,0]);
```

We compute the sum of a polynomial $h(x,y)$ by the command

```
>sum_polynomial_polygon(P,h);
```

Here P is a set of pairs of rational numbers, and $h = \sum_m h_m x^{m_1} y^{m_2}$ is entered as an expression in x, y .

Example 1. P is the square $\{[0, 0], [1, 0], [1, 1], [0, 1]\}$.

```
>square:= {[0,0],[1,0],[1,1],[0,1]};
```

```
>number_points_polygon(square);
```

4

The sum of values $x^5 y^5$ over the 4 integral points in the square is

```
>sum_monomial_polygon(square,[5,5]);
```

1

Example 2. Here P is a randomly chosen set of 15 points.

```
> P := {[77/8,97/59],[93/44,70/29],[0,25/12],[25/32,29/48],
[92/41,57/91],[9/4,1/7],[64/43,31/75],[91/17,33/86],[12/37,77/8],
[8/5,41/27],[80/67,11/9],[16/73,11/89],[41/20,43/88],
[32/49,59/23],[77/94,65/46]};
```

The number of integral points in the convex hull is 45.

```
>number_points_polygon(P);
```

45

The vertices of the convex hull \mathbf{p} of P (listed in counter-clockwise order) are obtained with the command:

```
>vertices_in_counter_clock_order:=proc(polygon)
>vertices_in_counter_clock_order(P);
[[0,25/12],[16/73,11/89],[9/4,1/7],[91/17,33/86],[77/8,97/59],
[12/37,77/8]]
```

We compute the sum of $x^{32} y^{32}$ over the set of integral points (x, y) of the convex hull \mathbf{p} of P .

```
>sum_monomial_polygon(P,[32,32]);
```

987532646688766560932727042325214847653263886

We compute the sum of $x^{32} y^{32} + 7$ over all the integral points (x, y) of the polygon \mathbf{p} . (the preceding number $+7$ times 45)

```
>h:= x^{32}y^{32}+7;
>sum_polynomial_polygon(P,h);
```

987532646688766560932727042325214847653264201

2.2. Weighted Ehrhart polynomial of a polygon. Our program computes also the weighted Ehrhart quasi-polynomial of a polygon. For brevity, we treat only the case where the weight is a monomial $h(x, y) = x^{m_1} y^{m_2}$. When the polygon is dilated by a non negative

integer t , and if q is a positive integer such that $q\mathbf{p}$ has integral vertices, the function of t given by

$$t \mapsto \sum_{(x,y) \in t\mathbf{p} \cap \mathbb{Z}^2} x^{m_1} y^{m_2}$$

is a quasi-polynomial $S(t) = \sum_{i=0}^{m_1+m_2+2} E_i(t)t^i$ of degree $m_1 + m_2 + 2$. The coefficients $E_i(t)$ are functions of t modulo q . This program computes these coefficients $E_i(t)$ in terms of the symbolic function $fmod(p * t, q)$ which stands for $(t \mapsto pt \bmod q)$. We can either obtain each individual coefficient $E_i(t)$ or the full weighted Ehrhart polynomial $S(t)$.

Here are the commands:

```
> coeff_t_Ehrhart_polygon(i,t,P,m);
```

The input consists of i an integer, t a letter, P a set of points and $m = [m_1, m_2]$ a pair of integers which represents the weight; the output is the coefficient $E_i(t)$.

```
> Ehrhart_polynomial_polygon(t,P,m);
```

Input is as in the previous command, except i is not needed. The output is the full Ehrhart polynomial $S(t)$.

Examples

```
> transsquare:={[-1/2,-1/2]{[1/2,-1/2],[1/2,1/2],[-1/2,1/2]}};
```

```
> coeff_t_Ehrhart_polygon(0,t,square,[0,0]);
```

1

```
> coeff_t_Ehrhart_polygon(0,t,transsquare,[0,0]);
```

```
-2*fmod(t, 2)+3/2+1/2*fmod(t, 2)^2
```

```
> Ehrhart_polynomial_polygon(t,square,[0,0]);
```

1 + 2 t + t^2

```
> Ehrhart_polynomial_polygon(t,transsquare,[0,0]);
```

(fmod(t, 2)-1)^2+(-2*fmod(t, 2)+2)*t+t^2

2.3. Experiments. The following experiments were done with a laptop, processor 1,86 GHz, RAM 782 MHz, 0,99 Go.

```
> A:={[( -567337)/102495, -1414975/95662], [1/3, 1/5], [-88141/20499, 12732/47831]};
```

```
> largeA:={ [1000*( -567337)/102495, 1000*( -1414975/95662)],
[1000*1/3, 1000*1/5], [-1000*88141/20499, 1000*12732/47831]};
```

```
> number_points_polygon(A);
```

```
> number_points_polygon(largeA);
34922612
```

In the next experiments, we indicate the time of computation T in seconds. The number of integral points in the rational triangle with vertices A is 36. If we dilate A by the factor 1000, we obtain the triangle $largeA$ where the number of points (34922612) is approximatively 10^6 times larger. Observe that we compute in 14 seconds the sum of the large degree monomial $h(x, y) = x^{64}y^{64}$ over the set of integral points of A , and that we compute in 16 seconds the sum of the same monomial over the integral points of $largeA$. The computation time is almost the same, although any computation by enumeration would be 10^6 times longer.

```
> T:=time(): sum_monomial_polygon(A, [32,32]); Time:=time()-T;

Time:= 15.516
```

Finally, we computed the weighted Ehrhart polynomial with weight $x^{32}y^{32}$ over the triangle with vertices $[[-567337/102495, -1414975/95662], [88141, 292844676/6833], [-88141/20499, 12732/47831]]$. We compute the coefficient of t^2 for example. The time of computation is 268 seconds. The result is too big to be printed here, as it involves many functions $f \bmod(c * t, D)$ where D runs through the denominators of the coordinates of the vertices of A (large numbers).

```
> T:=time(): coeff_t_Ehrhart_polygon(2,t, [[-567337/102495,
```

```

-1414975/95662], [88141, 292844676/6833], [-88141/20499,
12732/47831]], [32, 32]): Time:=time()-T;
Time := 268.266

```

3. MATHEMATICAL BACKGROUND

The first method is for a fixed polygon, the second one for the computation of the weighted Ehrhart quasi-polynomial.

3.1. First method: Brion's formula, Barvinok's decomposition into unimodular cones and iterated Laurent series. Let \mathfrak{p} be a convex polygon in \mathbb{R}^2 with rational vertices s_i , $1 \leq i \leq n+1$. We want to compute the sum

$$(1) \quad \sum_{x \in \mathfrak{p} \cap \mathbb{Z}^2} x^{m_1} y^{m_2}.$$

We start by observing that (1) is equal to the coefficient of $\frac{\xi_1^{m_1} \xi_2^{m_2}}{m_1! m_2!}$ in

$$\sum_{x \in \mathfrak{p} \cap \mathbb{Z}^2} e^{\langle \xi, x \rangle}.$$

Our method is based on Brion's formula (2). Brion's formula is the generalization of the following formula for the sum of geometric progressions over the interval $[A, B]$ (with $A \leq B$ integers):

$$\sum_A^B e^{n\xi} = \frac{e^{A\xi}}{1 - e^\xi} + \frac{e^{B\xi}}{1 - e^{-\xi}}.$$

For any rational polygon $\mathfrak{q} \subset \mathbb{R}^2$ define

$$S(\mathfrak{q})(\xi) = \sum_{x \in \mathfrak{q} \cap \mathbb{Z}^2} e^{\langle \xi, x \rangle}.$$

This is a meromorphic function near $\xi = 0$. Moreover the map $\mathfrak{q} \mapsto S(\mathfrak{q})(\xi)$ is a valuation on the set of rational polyhedra, and $S(\mathfrak{q}) = 0$ if \mathfrak{q} contains a line. Brion's formula is the following. Let \mathfrak{c}_i be the cone at vertex s_i of the polygon.

$$(2) \quad S(\mathfrak{p}) = \sum_{i=1}^{n+1} S(\mathfrak{c}_i).$$

Each term $S(\mathfrak{c}_i)(\xi) = \sum_{x \in \mathfrak{c}_i \cap \mathbb{Z}^2} e^{\langle \xi, x \rangle}$ in (2) is a meromorphic function near $\xi = 0$. The poles cancel and the sum is a holomorphic function of ξ . Thus we compute (1) as the coefficient of $\frac{\xi_1^{m_1} \xi_2^{m_2}}{m_1! m_2!}$ in the right-hand-side of (2). We actually compute the individual contribution of each cone \mathfrak{c}_i (associated to the vertex s_i) to the sum. The coefficient of

$\frac{\xi_1^{m_1}\xi_2^{m_2}}{m_1!m_2!}$ in the meromorphic function $S(\mathbf{c}_i)$ of two variables ξ_1, ξ_2 has no intrinsic meaning. Our method consists in applying **iterated Laurent series** expansions to $S(\mathbf{c}_i)(\xi)$ with respect to the variables ξ_1 then ξ_2 . We obtain a Laurent series $L(\mathbf{c}_i)$ in the ring $\mathbb{Q}[\xi_1, \xi_1^{-1}, \xi_2, \xi_2^{-1}]$ and we compute the coefficient $\frac{\xi_1^{m_1}\xi_2^{m_2}}{m_1!m_2!}$ in $L(\mathbf{c}_i)$.

Thus, in order to compute the contribution of a vertex s to the sum (2), we need to compute $S(\mathbf{c})(\xi)$ for the supporting cone \mathbf{c} . The crucial tool here is Barvinok's decomposition into unimodular cones. Actually, we use the following variant of Barvinok's decomposition, (procedure `signed_decomp`).

Let \mathbf{c} be a simplicial cone in \mathbb{R}^d . Let V_i , for $i = 1, \dots, d$, be the generators of \mathbf{c} . Let V be a vector in \mathbb{R}^d . We write $V = \sum_i u_i V_i$. We split $[V_1, \dots, V_d]$ into three parts, as follows.

$$L_+ := [X_1, \dots, X_k]$$

formed by the V_i such that $u_i > 0$,

$$L_- := [Y_1, \dots, Y_m]$$

formed by the V_i such that $u_i < 0$,

$$L_0 := \{Z_1, \dots, Z_b\}$$

formed by the V_i such that $u_i = 0$.

Then we have the equality of characteristic functions modulo characteristic functions of cones containing lines.

$$\begin{aligned} (-1)^{(k+1)}[\mathbf{c}] &= \sum_{i=1}^k (-1)^{i+1} [\mathbf{c}(X_1, \dots, X_{i-1}, -X_{i+1}, \dots, -X_k, V, L_-, L_0)] + \\ &\sum_{j=1}^m (-1)^{j+k} [\mathbf{c}(L_+, -V, -Y_1, \dots, -Y_{j-1}, Y_{j+1}, \dots, Y_m, L_0)]. \end{aligned}$$

Remark. This decomposition is not the stellar decomposition. It involves only cones of maximal dimension d . It avoids the dualizing trick of Brion.

Example. $\mathbf{c} = \mathbb{R}^+ e_1 \oplus \mathbb{R}^+ e_2$, $V = e_1 + e_2$, so that L_- and L_0 are empty and $k = 2$. Then

$$-[\mathbf{c}] = \mathbf{c}(V, -e_2) - \mathbf{c}(e_1, V) - \mathbf{c}[e_2, -e_2, e_1].$$

Indeed $[\mathbf{c}(e_2, -e_2, e_1)] - [\mathbf{c}]$ is equal to the characteristic function of the quadrant $(e_1, -e_2)$ minus that of the half-line $\mathbb{R}^+ e_1$. This is also the case for $[\mathbf{c}(V, -e_2)] - [\mathbf{c}(e_1, V)]$.

If we use a lattice vector V with sufficiently small coordinates in the basis (V_i) , the cones appearing in this decomposition have indices smaller than \mathbf{c} . One obtains such a *short* vector V by the Lenstra-Lenstra-Lovasz algorithm. By a repeated application of this decomposition, one obtains a decomposition of \mathbf{c} in a signed sum of unimodular cones \mathbf{c}_z (modulo cones containing lines). As $S(\mathbf{a}) = 0$ for a cone \mathbf{a} which contains a line, we can use this decomposition to compute $S(\mathbf{c})$.

For a unimodular cone \mathbf{c} , the sum $S(\mathbf{c})$ has a simple closed expression. Let (V_1, V_2) be primitive generators of the edges of \mathbf{c} and let s be its vertex. Let \tilde{s} be the unique integral point contained in the *semi-closed box*

$$\{s + t_1 V_1 + t_2 V_2, 0 \leq t_i < 1\}$$

If $s = s_1 V_1 + s_2 V_2$, then $\tilde{s} = \tilde{s}_1 V_1 + \tilde{s}_2 V_2$ with $\tilde{s}_i = \text{ceil}(s_i)$. Then

$$(3) \quad S(\mathbf{c})(\xi) = \frac{e^{\langle \xi, \tilde{s} \rangle}}{(1 - e^{\langle \xi, V_1 \rangle})(1 - e^{\langle \xi, V_2 \rangle})}.$$

In order to simplify the computation of iterated Laurent series, we introduce the analytic function

$$B(X, u) = \frac{e^{uX}}{1 - e^X} + \frac{1}{X} = - \sum_{n=0}^{\infty} \frac{b(n+1, u)}{(n+1)!} X^n$$

where $b(n, u)$ are the Bernoulli polynomials. Writing

$$(4) \quad \frac{e^{uX}}{1 - e^X} = B(X, u) - \frac{1}{X},$$

we obtain

$$S(\mathbf{c})(\xi) = A + G + R,$$

where

$$A = B(\langle \xi, V_1 \rangle, \tilde{s}_1) B(\langle \xi, V_2 \rangle, \tilde{s}_2)$$

is an analytic function of ξ ,

$$G := -\frac{1}{\langle \xi, V_1 \rangle} B(\langle \xi, V_2 \rangle, \tilde{s}_2) - \frac{1}{\langle \xi, V_2 \rangle} B(\langle \xi, V_1 \rangle, \tilde{s}_1),$$

$$R := \frac{1}{\langle \xi, V_1 \rangle \langle \xi, V_2 \rangle}.$$

We replace $\frac{1}{\langle \xi, V_1 \rangle}$ and $\frac{1}{\langle \xi, V_2 \rangle}$ by their iterated Laurent series expansion in the ring $R[\xi_1, \xi_1^{-1}, \xi_2, \xi_2^{-1}]$. For example, if $V_1 = [2, 1]$, we write

$$\frac{1}{2\xi_1 + \xi_2} = \frac{1}{\xi_2} \frac{1}{(1 + 2\xi_1/\xi_2)} = \frac{1}{\xi_2} \sum_{k=0}^{\infty} (-1)^k 2^k (\xi_1/\xi_2)^k.$$

We then replace $S(\mathbf{c})$ by the corresponding element in $\mathbb{Q}[[\xi_1, \xi_2, \xi^{-1}, \xi^{-2}]]$ and we take the coefficient of $\xi_1^{m_1} \xi_2^{m_2}$.

Remark The weighted Ehrhart polynomial can also be computed by this method. We did not write the corresponding algorithm in the Maple file, because we observed that a faster algorithm is given by the second method which we describe in the next section. However, let us explain what one should do. When the polytope \mathbf{p} is dilated in $t\mathbf{p}$, its vertices are dilated by t , while the edges of the cones at vertices do not change. Thus we have to compute

$$(5) \quad S(\mathbf{c}_t)(\xi) = \frac{e^{\langle \xi, \tilde{s}_t \rangle}}{(1 - e^{\langle \xi, V_1 \rangle})(1 - e^{\langle \xi, V_2 \rangle})}$$

where now s_t is the unique point with integral coordinates in the box

$$\{ts + u_1 V_1 + u_2 V_2, 0 \leq u_i < 1\}.$$

If $s = s_1 V_1 + s_2 V_2$, with $s_i = p_i/q_i$, we see that

$$s_t = [ts_1 + \text{mod}(-tp_1, q_1)/q_1, ts_2 - \text{mod}(-tp_2, q_2)/q_2].$$

The iterated Laurent series in ξ_1, ξ_2 has coefficients which are polynomials in t and the periodic functions $\text{mod}(tp_i, q_i)$. We extract the coefficient of $t^j \xi_1^{m_1} \xi_2^{m_2}$.

3.2. Second method. Weighted Ehrhart quasi-polynomial using local Euler-Maclaurin formula. We now recall the results of [2] and explain how they can be applied to the computation of the weighted Ehrhart quasi-polynomials. Let \mathbf{p} be a convex polytope in \mathbb{R}^d , with rational vertices. Let $h(x)$ be a polynomial function of degree r on \mathbb{R}^d . We want to compute the sum $\sum_{x \in \mathbf{p} \cap \Lambda} h(x)$ of values $h(x)$ over the set of integral points of the polytope \mathbf{p} .

The local Euler-Maclaurin formula has the following form.

$$(6) \quad \sum_{x \in \mathbf{p} \cap \Lambda} h(x) = \sum_{\mathbf{f} \in \mathcal{F}(\mathbf{p})} \int_{\mathbf{f}} D(\mathbf{p}, \mathbf{f}) \cdot h$$

where $\mathcal{F}(\mathbf{p})$ is the set of all faces of \mathbf{p} . For each face \mathbf{f} , $D(\mathbf{p}, \mathbf{f})$ is a differential operator of infinite degree with constant coefficients associated to \mathbf{f} . The operator $D(\mathbf{p}, \mathbf{f})$ is *local*, in the sense that it depends only on the intersection of \mathbf{p} with a neighborhood of any generic point of \mathbf{f} . The integral on the face \mathbf{f} is taken with respect to the Lebesgue measure on $\langle \mathbf{f} \rangle$ defined by the lattice $\mathbb{Z}^d \cap \text{lin}(\mathbf{f})$. Here $\langle \mathbf{f} \rangle$ is the affine span of the face \mathbf{f} and $\text{lin}(\mathbf{f})$ is the linear subspace parallel to $\langle \mathbf{f} \rangle$.

Let us recall the construction of the operators $D(\mathbf{p}, \mathbf{f})$. We denote by $\mathbf{t}(\mathbf{p}, \mathbf{f})$ the transverse cone to \mathbf{p} along \mathbf{f} . Using the standard scalar

product, $\mathbf{t}(\mathbf{p}, \mathbf{f})$ is described as the following affine cone in \mathbb{R}^d . Let $\text{lin}(\mathbf{f})^\perp$ be the vector subspace orthogonal to $\text{lin}(\mathbf{f})$. Then $\mathbf{t}(\mathbf{p}, \mathbf{f})$ is the orthogonal projection on $\text{lin}(\mathbf{f})^\perp$ of the supporting cone of \mathbf{p} along \mathbf{f} . The operator $D(\mathbf{p}, \mathbf{f})$ is defined in terms of the transverse cone $\mathbf{t}(\mathbf{p}, \mathbf{f})$, as follows.

For every rational affine cone $\mathbf{a} \subset V$, we construct in [2] an analytic function $\xi \mapsto \mu(\mathbf{a})(\xi)$ on \mathbb{R}^d . This construction depends on the choice of a scalar product. Here we use the standard scalar product. These functions $\mu(\mathbf{a})$ have nice properties which play a crucial role in our method. First, the assignment $\mathbf{a} \mapsto \mu(\mathbf{a})$ is a *valuation* on the set of affine cones with a given vertex. Second, it is *invariant under lattice translations*. Furthermore, $\mu(\mathbf{a}) = 0$ if \mathbf{a} contains a line.

We define

$$D(\mathbf{p}, \mathbf{f}) = D(\mu(\mathbf{t}(\mathbf{p}, \mathbf{f})))$$

as the differential operator of infinite degree with constant coefficients, with symbol $\mu(\mathbf{t}(\mathbf{p}, \mathbf{f}))(\xi)$. In other words, if $\xi = (\xi_1, \dots, \xi_d)$, we obtain $D(\mathbf{p}, \mathbf{f})$ by replacing ξ_i by $\frac{\partial}{\partial x_i}$ in the Taylor series of $\mu(\mathbf{t}(\mathbf{p}, \mathbf{f}))(\xi)$.

For any positive integer t , we consider the dilated polytope $t\mathbf{p}$ and the corresponding sum

$$S(t\mathbf{p}, h) = \sum_{x \in t\mathbf{p} \cap \Lambda} h(x).$$

From (6), it follows easily that the function $t \mapsto S(t\mathbf{p}, h)$ is given by a quasi-polynomial: there exist periodic functions $t \mapsto E_i(\mathbf{p}, h, t)$ on \mathbb{N} such that

$$(7) \quad S(t\mathbf{p}, h) = \sum_{i=0}^{d+r} E_i(\mathbf{p}, h, t) t^i$$

whenever t is a positive integer. Moreover the coefficients $E_i(\mathbf{p}, h, t)$ are computed using the functions $\mu(\mathbf{t}(t\mathbf{p}, t\mathbf{f}))$. Indeed, let s be the vertex of $\mathbf{t}(\mathbf{p}, \mathbf{f})$ so that $\mathbf{t}(\mathbf{p}, \mathbf{f}) = s + \mathbf{t}_0$. Then the dilated transverse cone is $\mathbf{t}(t\mathbf{p}, t\mathbf{f}) = ts + \mathbf{t}_0$. As $\mathbf{a} \mapsto \mu(\mathbf{a})$ is invariant under lattice translations, we have

$$\mu(\mathbf{t}((t+q)\mathbf{p}, t\mathbf{f})) = \mu(\mathbf{t}(t\mathbf{p}, t\mathbf{f})),$$

if q is an integer such that qs is a lattice point for the projected lattice, or equivalently, such that $q < \mathbf{f} >$ contains a lattice point. Thus, the coefficients $E_i(\mathbf{p}, h, t)$ depend only on $t \bmod q$, where q is the smallest integer such that $q\mathbf{p}$ has integral vertices.

When \mathbf{a} is a *unimodular* affine cone of dimension 1 or 2, the functions $\mu(\mathbf{a})$ have an explicit form, in terms of the functions $B(X, u)$ introduced in (4).

Let \mathfrak{d} be a one dimensional affine cone of the form $(s + \mathbb{R}_+)V$ where V is a primitive vector and $s \in \mathbb{Q}$. We have

$$(8) \quad \mu(\mathfrak{d})(\xi) = B(\langle \xi, V \rangle, \text{ceil}(s) - s).$$

Let \mathfrak{a} be a two dimensional *unimodular* affine cone. Let V_1, V_2 be primitive generators of its edges, such that $\det(V_1, V_2) = 1$. For $\xi = (\xi_1, \xi_2) \in \mathbb{R}^2$, let $y_i = \langle \xi, V_i \rangle$, for $i = 1, 2$, be the coordinates of ξ relative to the dual basis (V_1^*, V_2^*) . We write the vertex of \mathfrak{a} as $s_1V_1 + s_2V_2$ with $s_i \in \mathbb{Q}$. Let $\epsilon_i = \text{ceil}(s_i) - s_i$, and let $C_i = \frac{\langle V_1, V_2 \rangle}{\langle V_i, V_i \rangle}$, for $i = 1, 2$. With these notations, we have

$$(9) \quad \mu(\mathfrak{a})(\xi) = \frac{e^{\epsilon_1 y_1 + \epsilon_2 y_2}}{(1 - e^{y_1})(1 - e^{y_2})} + \frac{1}{y_1} B(y_2 - C_1 y_1, \epsilon_2) + \frac{1}{y_2} B(y_1 - C_2 y_2, \epsilon_1) - \frac{1}{y_1 y_2}.$$

The function $\mu(\mathfrak{a})(\xi)$ is actually analytic, although this is not obvious on (9). In order to compute the contribution of a vertex s of \mathfrak{p} to the sum (6), we need to compute $\mu(\mathfrak{c})(\xi)$ when \mathfrak{c} is the two-dimensional supporting cone at s . The crucial tool here is Barvinok's decomposition into unimodular cones. The valuation property of $\mathfrak{a} \mapsto \mu(\mathfrak{a})$ makes it possible to reduce the computation to the unimodular case, and use (9). Notice that (9) returns a function of the relative coordinates (y_1, y_2) , which we must convert back to a function of the standard coordinates (ξ_1, ξ_2) , in order to add the contributions of the various unimodular cones in Barvinok's decomposition. Actually, since $\mu(\mathfrak{a}) = 0$ if the cone \mathfrak{a} contains a line, we use the variant of Barvinok's decomposition described in the first method.
